Abstract

The implementation of macroprudential supervision, significantly tighter capital regulation in developing economies, has recently been debated, which focuses on reducing bank risk-taking and promoting financial stability in the banking sector. Our study investigates the impact of prudential capital on commercial banks' risk-taking in Indonesia. We employed a GMM system approach to analyze bank and macro level data from 2004 to 2019. Our result confirms that appropriate capital regulations for reducing bank risk-taking are heterogeneous. Traditional capital ratios decrease bank risk-taking. However, the risk-based capital ratio shows an unexpected affirmative effect. Implementing macroprudential policy instruments of capital buffer effectively manages bank risk, and so does the regulatory capital pressure variable. The results are intimate for guiding commercial banks' risk management and capital effectiveness.

Keywords: macroprudential policy, financial stability, bank risk-taking, prudential capital buffer, regulatory capital pressure

JEL Classification: E58, G21, G28

Introduction

Capitalization has been essential in mitigating bank risk since the commencement of a universal model, the 1988 Basel I, 2004 Basel II, and 2010 Basel III accords. Implementing Basel III required regulators to maintain the capitalizations of their commercial banks (Abbas, Ali, et al., 2021; Jiang & Zhang, 2017). Generally, Basel III has three kinds of capital regulation: capital adequacy ratio, the risky asset of tier-one capital ratio, and tier-one standard equity ratio. It promotes that the most analyzed capitalization topics are around these three ratios. Das & Rout (2020) found an affirmative correlation involving bank risk activity and adequacy of capital. Anginer et al. (2021), Illueca et al. (2022), Mateev et al. (2021), Le et al. (2022), Son et al. (2022) show a positive correlation between equity ratio on financial stability of commercial banks or adversely affects bank risk-taking. However, they generally utilized risk-based and non-risk-based capital requirements to examine how market capitalization affected bank risk-taking. They do not include macroprudential capital instruments in mitigating financial risk and promoting recently implemented stability.

Nowadays, macroprudential policy has an important position in the financial aspects of many countries (Davis et al., 2022; De Schryder & Opitz, 2021; Gaganis et al., 2020; Igan et al., 2022). Implementing macroprudential policy instruments is not a new regulation in the financial system. However, the adjustment of macroprudential policy instruments is intensive, notably in the light of the worldwide downturn of 2007–2008 (Maatoug et al., 2019; Noman et al., 2017; Ovi et al., 2020; Tongurai & Vithessonthi, 2020; Zhang et al., 2018). The period of the most implemented prudential policy is also the beginning year for the implementation of macroprudential policy in developing countries to mitigate and prevent future bank risk-taking, promoting financial stability.

Issues regarding implementing the macroprudential policy have emerged among the studies of scholars and policymakers (Gaganis et al., 2020; Igan et al., 2022). The majority of earlier investigations emphasized the variability impact of time-varying policy and the implementation of macroprudential instruments (Ćehajić & Košak, 2022; Davis et al., 2022; De Schryder & Opitz, 2021;

Fabiani et al., 2022; Gaganis et al., 2020; Igan et al., 2022). In particular, Ćehajić & Košak (2022), Fabiani et al. (2022), and De Schryder & Opitz (2021) show an inverse effect of reserve requirements on the credit supply of commercial banks. Ćehajić & Košak (2022) use monthly panel data of firms' level from January 2009 to February 2011, revealed that a more tightening saving requirements produce a more quality of credit to the small and medium enterprises (SMEs) in European countries. Fabiani et al. (2022) employing quarterly panel data from second quarter of 2005 to second quarter 2008 to analyze the a source of bank loans over the implementation of macropduential policy in Colombia. They conclude that, an increase in the reserve requirements worsens credit supply especially for non-profitable firms. It means that the policy regarding reserve requirements reducing bank risk-taking. Furthermore, De Schryder & Opitz (2021) examine the effect of typical macroprudential on bank lending in 13 European countries using panel data from 1999 to 2018. They found that decrease in the loosing of reserve requirements reduce consumer credit to GDP and bank credit to GDP ratio in selected EU economies.

Other studies on capital requirements by Gaganis et al. (2020) investigate the variability effect of ten macroprudential instruments on bank-risk taking for 50 selected countries. They conclude that implementing macroprudential instruments reduces bank risk-taking, boosting financial stability. Igan et al. (2022) support Gaganis et al. (2020) that tighter reserve requirements and regulations weaken bank risk-taking across 52 economies. However, Davis et al. (2022) provide an inverse effect of that macroprudential instrument on profitability for over 92 countries.

Most of previous studies focused on the use central bank reserve requirements. Moreover, they employed group of countries that may reveal different characteristics of each economy. Other, so far as we are concerned, research on the evaluation of macroprudential policy instruments focused on capitalization such as prudential buffer and regulatory capital pressure across several types with a single country to reduce bias caused by different scale of economies, are scarce. Thus, our study tries to fill the gap by examine the effect of capitalizations which focused on the effectiveness of prudential capital buffer as one of macroprudential policy instruments and regulatory capital pressure on bank risk-taking in strengthening financial stability in Indonesia.

This study comprises the implementation impact of prudential and non-prudential capital on bank risk-taking of Indonesian commercial banks. Furthermore, We operate the system of generalized method of moments (GMM-SYS) found by Arellano & Bond (1991) and Blundell & Bond (1998) in accordance to limit the potential endogeneity issues. In various ways, our manuscript contributes to the body of knowledge on capitalization of bank risk-taking. First, this study covers the period before 2007 and after 2009 and using six different groups of commercial banks data for getting a deeper analysis. Second, other studies use a non-risk-adjusted capitalization ratio, while we employ both risk-adjusted capitalization ratios and prudential capital buffers to cover the implementation of macroprudential policy instruments. Third, we also contribute to extending the capital buffer ratio by adding regulatory capital pressure to provide a deeper analysis of capitalization for specific domestic-systemically important banks (D-SIB) regulations. Finally, the results are essential for policymakers to observe the variability effect of different capitalizations and provide a new guideline for banking stability.

The complete procedure of this study is divided into different sections: Part two is devoted to methodology, the third chapter informs the analysis and discussion of the research result, and the last section concludes the overall manuscript.

Research Method

Data

This study used yearly panel data containing two types of data sets, bank scope level, and macroeconomic level, from 2004 to 2019. The original dataset was mainly extracted from the official site of the Central Bank of Indonesia (BI), the Financial Service Authority (FSA) of Indonesia, and the Indonesian Central Bureau of Statistics. This study analyzed the risk-taking of 18 conventional

commercial banks in Indonesia. Generally, Indonesia categorizes banks into six groups. We used the top three sizes of banks in each group. The size of banks used in this study is size data in 2019 as the last period of the reported bank to the FSA.

Model Specification

We built an empirical model with a few associated variables because we wanted to investigate the impact of capitalization on risk-taking experimentally. The dependent variable is bank risk-taking, which uses the Z-score as a proxy. We divide the independent variables into three groups. First, there are bank-specific operational factors to consider, such as bank size, amenities and infrastructure, and operational performance. Second, capitalization is the primary variable estimate of this study, which focuses on four types of capitalization, such as traditional capital ratio (TCR), risk-based capital ratio (RCR), and capital buffer ratio (CBR). We add the extended variable, the regulatory capital pressure (RCP), to provide a more specific analysis. The third is macroeconomic control variables, which include inflation rate and real GDP growth. Thus, we employ a general regression model as follows:

$$Z_{it} = \alpha + \beta BSC_{it} + \vartheta CAP_{it} + \emptyset MAC_{it} + \varepsilon_{it}$$
 (1)

Where i = 1 to N and t = 1 to T, N is the figure of individual banks, T is time, and α , β , ϑ , \emptyset are approximated parameters. Z_{it} refers to the risk-taking for bank i at time t, which Z-score as a proxy.

 BSC_{it} represents bank characteristics for bank i at time t. CAP_{it} indicates the effect of types of capitalization. MAC_{it} shows the effect of macroeconomic conditions, and ε_{it} represents the error term.

Variable Measurement Bank Risk-Taking

We employ bank risk-taking as an explained variable by calculating Z-score as a primary ration. The essential idea of the use of Z-score measurement is the capitalization and returns variability of the bank. It reveals efficiency with minimum insolvency of a bank (Adu, 2022; Gaganis et al., 2020). We determine Z-score as follows (Illueca et al., 2022; Moudud-Ul-Huq, 2019; Son et al., 2022; Toh & Zhang, 2022):

$$Z_{it} = \frac{ROA_{it} + E_{it}/TA_{it}}{\delta ROA_{it}}$$

Where Z_{it} represents the risk score of bank i at time t. ROA_{it} represents the bank i's asset returns at time t. We calculate ROA as follows:

$$ROA_{it} = \frac{Earning Before Tax_{it}}{Total Asset_{it}} \times 100\%$$

The E_{dit}/TA_{it} measures the equity to total assets ratio of bank i at time t. δ ROA $_{it}$ measures the standard deviation of ROA $_{it}$. Higher Z-score increases the probability and capitalization level, decreasing bank risk-taking. To represents a higher Z-score as a more advanced bank risk-taking, we multiply the Z-score by the value of -1.

Bank Specific Control

We calculate bank-specific supervision using bank size (BAS), asset composition (ASC), and operational efficiency (OPE) as independent variables. The bank size variable represents that bigger banks could be willing to take on more risk due to their more significant market clout. Furthermore, this study uses total assets to represent the bank size variable. To show the effect of asset composition, we substitute by using the loan-to-asset ratio. The use of the loan-to-asset ratio that it controls asset composition as a metric of bank lending behavior. Finally, we employ the cost-to-income proportion as one of the characteristics peculiar to a certain bank to measure the bank's operational efficiency. Operational costs and operating income are divided to determine the cost-to-income ratio.

Capitalization

Capitalization strengthens the financial system while preventing systemic risk buildup by restricting financial institutions' excessive risk-taking (Abbas, Ali, et al., 2021; Adu, 2022; Agénor & Silva, 2021; Malovaná & Ehrenbergerová, 2022). We examine four kinds of capitalization to provide a different effect of capitalization on bank risk-taking. First, the traditional capital ratio (TCR) is measured by total equity by total assets as follows:

$$TCR_{it} = \frac{Total \ Asset_{it}}{Total \ Equity_{it}} \times 100\%$$

Second, risk-based capital ratio (RCR) as a weight of banks and minimum regulatory requirements is an essential strategy in bank risk-taking (Broll et al., 2018; Das & Rout, 2020). We calculated RCR as follows:

$$RCR_{it} = \frac{Tier \ 1 \ Capital_{it} + Tier \ 2 \ Capital_{it}}{Risk-Weighted \ Asset_{it}} \times 100\%$$

Whereas i denotes the bank and t denotes the amount of time, Equity capital comprises Tier 1 capital, commonly referred to as required reserves, shares outstanding, intellectual properties, and verified earnings reserves. Reserves retained earnings and overall liability reserves that have not been audited make up Tier 2 capital.

Third, the capital buffer ratio (CBR) indicates changes in banks' capitalization levels due to capital regulations (Illueca et al., 2022; Jiang et al., 2020; Jiang & Yuan, 2022). By influencing borrowers, we anticipate that a more excellent BCB ratio will decrease bank risk-taking and boost financial stability. According to this analysis, more stringent capital regulations, such as underwriting standards, sectoral capital buffers, and countercyclical availability of capital, will raise funding costs or restrain credit expansion (Auer et al., 2022; Bagntasarian & Mamatzakis, 2019). This circumstance could lead to stricter credit requirements supported by borrowers and could lower loan demand. Additionally, the capital buffer can help banks' financial standing and reduce their risk-taking distribution by obtaining loans from customers who adhere to stricter restrictions.

We add an extended variable, the regulatory capital pressure (RCP). Because we use several commercial banks with varied capital structures as a sample, we include numerous institutions in the list of domestic - systemically important banks (D-SIB). We introduce regulatory capital pressure (RCP) as an independent variable to match the bank macroprudential policy instrument. We determine RCP as the difference between the minimum regulatory norm for commercial banks, including D-SIB and other banks, and the capital adequacy ratio (CAR) and standard deviation of CAR. RCP is calculated as follows for bank i at time t (Zhang et al., 2018):

$$RCP_{it} = CAR_{it} - \delta CAR_i - 8\%$$
 For other banks;
 $RCP_{it} = CAR_{it} - \delta CAR_i - (9\% \text{ to } 10.5\%)$ For D-SIB.

Furthermore, there is a shortage of research on the connection between capitalization (capital buffer ratio and regulatory capital pressure) and bank risk-taking.

Macroeconomic Control

This analysis uses the pace of Indonesian GDP growth and the rate of inflation macroeconomic control variables. GDP denotes a variation in economic activity during the business cycle, which most likely influences the performance of a country's financial institutions (Abbas, Ali, et al., 2021; Abbas, Masood, et al., 2021; Anginer et al., 2021; Banai et al., 2022; Conti et al., 2022; Ginting & Widyawati, 2022; Zhang et al., 2018). The consumer price index will be utilized as a stand-in for the inflation rate in this study. The actual economy and financial stability of a nation are both impacted by inflation since it has an inverse relationship with both (Auer et al., 2022; Mateev et al., 2022; Ongena et al., 2022). Finally, we also put interest rate by employing the Bank Indonesia rate to analyze the effect of the rate of return. We expect a tighter interest rate would reduce bank risk-taking (Adão et al., 2022; Bongiovanni et al., 2021). GDP growth, consumer pricing information, and interest rate are taken from the official website of the Indonesian Central Bureau of Statistics and Bank Indonesia.

Estimation Strategy

We use a panel data simulation to study the impact of capitalization on bank risk-taking because it incorporates the nature of bank risk-taking and the potential endogeneity issue across variable estimates. Moudud-UI-Huq (2019) demonstrates that the static model based on the random and fixed effect model has a significant econometric imbalance and contradictory conclusions since there is an association between lag changes in the dependent variable. Therefore, in a dynamic situation, we employ a generalized method of moments (GMM) that regulates the endogeneity of the

lag-dependent variable. GMM lowers omitted bias concerns, regulates unaccounted heterogeneity issues, and manages the measurement error problem in panels (Abbas, Masood, et al., 2021; Moudud-Ul-Huq, 2019; Son et al., 2022).

It is noteworthy that our research uses a System-GMM estimator that was propounded by Arellano and Bond (1991) and Blundell and Bond (1998) to develop accurate estimators. When there is a lack of time sequence (t) and a large cross-section (N), the System-GMM is the best estimator, according to Noman et al. (2017). Additionally, System-GMM has improved estimation capabilities that can estimate the explanatory variable coefficients. The transformed econometric model by the System-GMM in the following equation:

$$Z_{it} = \alpha + \beta BSC_{it} + \vartheta CAP_{it} + \emptyset MAC_{it} + \gamma_{t} + \gamma_{i} + \epsilon_{:*}$$
 (2)

Where γ_t reflects the time effect, which has i=1 to T and γ_i is the bank effect, which has t=1 to N, and α , β , ϑ , \emptyset are estimated parameters. Finally, ϵ_{it} is an error term of model estimates.

Result and Discussion

Issues on the connection between bank capitalization and risk-taking emerge every period, primarily when the business cycle occurs remarkably. Most studies estimate the determinants of bank risk-taking, which focus on asset measurements such as the total or size and the adequacy effect (Andries et al., 2020; Broll et al., 2018; Das & Rout, 2020; Kosenko & Michelson, 2022; Le et al., 2022; Mateev et al., 2021; Noman et al., 2017). It merely shows that the studies focused on the effect of prudential capital are scarce. Thus, we dedicate our study to concern on applying bank capital buffer and regulatory capital pressure to capture newly prudential regulations implemented recently.

Source: Authors' computation (2022)

We begin our discussion based on the result of the statistic descriptive in table 2. We apply 288 observations based on 18 banks as cross-sections and 16 years of each bank. Over the sample period, Bank size varies from the bank with higher and lower assets. Banks with maximum size are primarily categorized as state-owned commercial banks. Averagely, the capital buffer ratio of commercial banks is 33 percent, implying that the proportion of capital buffer was at a well-managed level. The minimum point is 1.16 percent, mainly at the beginning of the sample in 2004, and it increased to the maximum in 2019. The regulatory capital pressure is 3.7 percent, indicating that most banks are not included in domestic-systemically important banks (D-SIB). The result of summary statistics is presented in table 2.

We also examine the correlation coefficient of each variable estimate. The result above the critical value (α =0.01, 0.05, and 0.1) confirms the presence of correlation (Abbas, Ali, et al., 2021; Abbas, Masood, et al., 2021; Anginer et al., 2021; Zhang et al., 2018). Our analysis was confirmed through the number of correlation coefficients above the critical value. The result reveals that traditional capital and risk-based capital ratio are statistically significant. We confirm the result of Abbas, Ali, et al. (2021) and Defung & Yudaruddin (2022). The capital prudential buffer variables, such as capital buffer and regulatory capital pressure, correlate similarly with bank risk-taking (Abbas, Ali, et al., 2021). The coefficient correlation analysis is presented in table 3.

The important of the Hansen J-test for the correctness of the overidentifying restriction and endogeneity problem is provided by the usage of the GMM system estimate. Table 4 column models 1 through 5 show that the Hansen J-test outcome is not statistically significant. The test's lack of significance guarantees that, with the overidentifying constraint in place, the incorporation of instrumental variables for managing the endogeneity problem is legitimate. We get to the conclusion that there is absolutely no link between the instruments and the standard errors, and we address the endogeneity issue within those findings from our approach.

Source: Authors' computation (2022)

Table 4 shows the result of the causality investigation result of bank risk-taking determinants. We provide five models due to the cross variability of capitalization effects. Since we divide the models according to the different effect of a single capitalizations, we also provide three variable groups of each model. The first group is bank specific control variables. We employ three variables of bank specific control such as banks size, asset composition, and operational efficiency. The result shows that bank size has significant and inverse effect in model 1, model 4, and model 5. It indicates that the bigger asset of banks can effectively decrease bank risk-taking. Our finding supports the study of Abbas, Masood, et al. (2021) who mentioned that the size of bank could decrease non potential credit of banks, therefore, decrease the risk-taking. However, other bank specific control variables such as asset composition and operational efficiency are supposed to have an insignificant effect on ban risk-taking. It merely shows that composition of asset and cost of operation do not directly affect on risk of a bank. However, it would be following some channels to support bank financial stability.

Model 1 shows the traditional capital ratio's negative and emprirically significant effect on bank risk-taking. Equity-to-total asset ratio indicates the use of the company's capital in financing the company's assets. It means that an increase in the capital in the total equity would decrease the risk banks have taken while the total asset and other factors remain constant (Abbas, Masood, et al., 2021; Conti et al., 2022; Le et al., 2022). We refuse the previous result of Abbas, Masood, et al. (2021). However, Our findings agree with the results of Das & Rout (2020), who suggest that an increase in equity would improve the mean cost of capital. However, a rise in the lending rate simultaneously would decrease bank risk-taking. Besides, Le et al. (2022) explain that an increase in the bank's

portfolio would decrease bank risk-taking. The coefficient estimates of the traditional capital ratio of model 1 were confirmed by model 5, with overall capitalization variables analyzed.

The standard deviation is shown in brackets (), and the significance levels at 1%, 5%, and 10% are indicated by *, **, and ***, respectfully (Source: Author's Computation).

Inversely, the risk-based return rate on capital has a favorable and statistically significant effect. It is interesting because most previous studies suggested that an increase in capital adequacy would decrease bank risk-taking. However, our estimates indicate that increasing the risk-based capital requirement would enhance banks' risk. This result is different explains with the previous research by Son et al. (2022). They explain that with an increase in the bank capital requirements for the risk-weighted asset, the bank would be more stable due to the moral hazard hypothesis, decreasing bank risk-taking. However, we support the finding of Das & Rout (2020), who suggests the reason behind the affirmative correlation between the risk-weighted capital ratio and bank risk-taking due to the "too big to fail attitude" and other errors in screening and monitoring. Furthermore, following the intuition of Agénor & Silva (2021), a tighter risk-weighted capital ratio passed through its optimal point (whose marginal effect is zero), and the return weakens as the number of loans decreases.

The capital buffer ratio (CBR) shows a tighter regulation with additional capital requirements for commercial banks and reduced bank risk-taking (Abbas, Ali, et al., 2021; Moudud-Ul-Huq, 2019).

Model 3 in table 4 reveals a single capitalization variable effect on bank risk-taking. The calculated correlation of CBR is contrary and quantitatively relevant at a 1 percent confidence ratio. The coefficient of -0.2899 means a-1% rises in the required capital buffer by the central bank, and the risk-taking by commercial banks would decrease by around 28.99 percent. This result corroborates the earlier researches of Zhang et al. (2018), Abbas, Masood, et al. (2021), Illueca et al. (2022) in the case of the pre-adoption period of Spanish private banks, Jiang & Zhang (2017) in the case of upper tail risk for Chinese banks. Following the transmission from Auer et al. (2022), banks are more likely to charge higher interest rates in response to a rise in the capital buffer proportion. It would decrease the lending rate, especially the non-performing intermediation. Therefore, the decrease in non-performing intermediation reduces bank risk-taking.

Model 4 presents a single capitalization effect of regulatory capital pressure on bank risk-taking. The coefficient of regulatory capital pressure is also negative (-0.1460) and statistically significant at a one percent confidence level. An increase in regulatory capital pressure weakens bank risk-taking. The impact of RCP of simultaneous capitalization effect in model 5 confirms it. Zhang et al. (2018) reveal the transmission of capital pressure affecting the bank's risk-taking through the central bank reserve requirement channel. They explain that a higher regulatory capital pressure is due to higher reserve requirements, decreasing bank risk-taking.

Finally, macroeconomic control variables show various effect on bank risk-taking. GDP provides positive and significant effect in model 2, model 3, and model 4. We present this unexpected effect due to procyclicality of financial institutions. Banks tend to lend more when they pay attention a positive signal and abide the precautionary principle. Therefore, the booms of credit would increase the risk in financial institutions. The inflation rate negatively affects bank risk-taking especially in model 1, model, 4, and model 5. Our result supports the study of Son et al. (2022). The last macroeconomic control is interest rate. The result presents an affirmative and significant effect of interest rate on bank risk-taking. Overall, the variability of macroeconomic variables affect bank risk-taking in Indonesia.

Conclusion

Governments all across the globe are being compelled to improve their financial soundness as a consequence of the worldwide turmoil. To protect the financial system from disasters, the banking industry needs more stringent capital regulations. Therefore, capitalizations-based tools are a part of macroprudential policy and are used to raise the emergency preparedness signal. We present an analysis of capitalization's impact on bank risk-taking with the case of Indonesian commercial banks.

Our finding shows that single and overall cross-capitalization variables are consistent. The variable of the traditional capital ratio effectively weakens bank risk-taking. However, the risk-based capital ratio has an inverse towards our expected sign, which an improvement in terms of the risk-based capital ratio improves bank risk-taking. The macroprudential instruments for the capitalization aspect, the capital buffer ratio for commercial banks, reduces the risk probability. Furthermore, our extended prudential capital buffer and regulatory capital pressure for domestic-systemically important banks (D-SIB) confirm the decrease in bank risk-taking. Therefore, we suggest maintaining the performance of macroprudential capital instruments for further analysis and policy decision-making.

This study is restricted to a review of the impact of prudential and non-prudential capital buffers on Indonesian banking sector financial stability. Our study is indeed confined to the bank industry in terms of measuring the financial stability variable and it does not yet employ quantity of materials to demonstrate overall financial stability across Indonesia's numerous financial institutions. Additionally, the cross-sectional data set consists of 18 commercial banks, each representing a different Indonesian bank group, and the time series data utilized is restricted to pre-pandemic datasets. Therefore, future studies may create a more thorough measure of financial stability that takes into account financial stability overall, the fluctuations of financial stability throughout an outbreak, and the number of

institutions that would be more suitable to reflect a representative of all Indonesian commercial banks.

Acknowledgement
